

Designation: F3122 – 14

Standard Guide for Evaluating Mechanical Properties of Metal Materials Made via Additive Manufacturing Processes¹

This standard is issued under the fixed designation F3122; the number immediately following the designation indicates the year of original adoption or, in the case of revision, the year of last revision. A number in parentheses indicates the year of last reapproval. A superscript epsilon (ϵ) indicates an editorial change since the last revision or reapproval.

1. Scope

1.1 This standard serves as a guide to existing standards or variations of existing standards that may be applicable to determine specific mechanical properties of materials made with an additive manufacturing process.

1.2 As noted in many of these referenced standards, there are several factors that may influence the reported properties, including material, material anisotropy, method of material preparation, porosity, method of specimen preparation, testing environment, specimen alignment and gripping, testing speed, and testing temperature. These factors should be recorded, to the extent that they are known, according to Practice F2971 and the guidelines of the referenced standards.

1.3 The following standards are not referred to directly in the guide but also have information that may be useful in the testing of metal test specimens made via additive manufacturing: A370, A1058, B211, B348, B557, B565, B724, B769, E3, E6, E7, E290, E467, E468, E837, E915, E1049, E1823, E1942.

1.4 *Units*—The values stated in SI units are to be regarded as the standard. No other units of measurement are included in this standard.

1.5 *This standard does not purport to address all of the safety concerns, if any, associated with its use. It is the responsibility of the user of this standard to establish appropriate safety and health practices and determine the applicability of regulatory limitations prior to use.*

3. Terminology

3.1 Definitions:

- 3.1.1 Terminology relating to additive manufacturing in Terminology F2792 shall apply.
- 3.1.2 Terminology relating to additive manufacturing in ISO/ASTM 52921 shall apply.

4. Measuring Deformation Properties

4.1 Tension:

- 4.1.1 The procedures outlined in Test Methods E8/E8M, E21, E1450, ISO 6892-1, ISO 6892-2, ISO 15579, and ISO 19819 explain guidelines for tension testing under various conditions to determine a material's yield and tensile strengths. All are applicable to materials made additively, but sheet-, wire-, and rod-shaped specimens with small diameters are difficult to build through an additive process.
- 4.1.2 In the tension testing procedures outlined in Test Methods E292 (for determining a material's rupture strength) and Practice E740 (for determining metal plate yield strength), Test Methods E8/E8M's methods are followed, but the samples are first prepared with a notch or surface-crack before subjecting them to tension. While Test Method E292 is applicable to materials made additively, it must be noted that thin specimens

made according to Practice E740 may be challenging to make in some additive manufacturing processes.

4.1.3 Two ISO Standards, ISO 26203-1 and ISO 26203-2, describe testing sheet metal, such as the material used for automotive bodies, at high strain rates. These standards are not applicable to materials made additively, because sheet material would not be made with such a process.

4.2 Compression:

4.2.1 The procedures outlined in Test Methods E9 and Practice E209 describe the basic method for uniaxial compression testing of metallic samples at various temperatures. The procedures are used in determining a material's compressive yield strength and compression strength. These standards are applicable to materials made additively, but not all of the sample types (thin sheets) can be successfully built through an additive process.

4.3 Bearing:

4.3.1 The procedures outlined in Test Method E238 describe the method used to determine bearing yield strength and bearing strength for a rectangular metal specimen containing a hole for a bearing pin. This standard is applicable to materials made additively, but the surface finish requirements and some thickness requirements for the specimen may be problematic for some additive manufacturing processes.

4.4 Bend:

4.4.1 Practice E209 describes the methods that determine the limit of plastic deformation allowed in a metallic material during bending. The criterion used to evaluate the quality of materials includes their ability to resist cracking or other surface irregularities. ISO 7438 includes plastic deformation methods to evaluate a material's ability to resist cracking. ISO 7438 also includes the methodology behind measuring the bending strength, the limit of elasticity bending, bending moments and the bending angle using plastic deformation methods. These standards are also applicable for metal based additive manufactured parts.

4.5 Modulus:

4.5.1 The following section includes standard test methods to evaluate elastic moduli and Poisson's Ratio. These test methods could be used in the determination of elastic properties of metal based AM materials.

4.5.2 Tension tests, as described by Test Methods E8/E8M, can be used to determine the Young's modulus, tangent modulus and chord modulus of AM structural materials. Test Method E111 describes how to determine the elastic material property based on the tension test (E8/E8M) or compression test (E9). This standard also can be used to determine the Young's modulus, tangent modulus and chord modulus using the stress-strain behavior.

4.5.3 Poisson's ratio is the ratio of transverse strain to the corresponding axial strain, and is an intrinsic material property. This ratio can be useful to further describe any anisotropic behavior of additively produced bulk materials. Test Method E132 describes the method to determine Poisson's ratio based on the results of a tension test on a rectangular specimen.

4.5.4 Test Method E143 describes the procedure for calculating the Shear modulus on specimens with a round shape,

such as a solid cylinder or a tube. This standard describes the use of an externally applied torque, and subsequent calculation and determination of the Shear modulus. Shear modulus is a helpful property used in the design of rotating technical parts, such as, rotating shafts, springs or screws.

4.5.5 Two alternative methods to determine the dynamic Young's modulus, Shear modulus and Poisson's ratio are described in Test Methods [E1875](#) and [E1876](#). These test methods include guidelines for making measurements at temperatures between -195 to 1200°C. Additionally, formulas can also be found that are used to calculate the dynamic elastic properties based on the elastic resonance of the specimens. Both Test Methods [E1875](#) and [E1876](#) require specimens that possess specific mechanical resonant frequencies. The difference between these two standards is the application of a transducer, which transforms a cyclic electrical signal from the oscillator into a mechanical force on the specimen.

4.6 Hardness:

4.6.1 The following indentation tests may help to define the hardness of additive manufactured parts. Hardness is not a fundamental material property, but the wide variety of hardness test methods in use today help predict a material's resistance to plastic deformation or wear resistance, or both against abrasive stress. Due to the subjective nature of the present hardness tests, the desired hardness test and loading size must be specified prior to testing. Regardless of the hardness test specified, all methods require preparation of the material's surface before testing. Prior to testing, the sample thickness size must also be considered, because if the sample is too thin, the hardness value measured can be inaccurate.

4.6.2 Brinell hardness testing defines the determination of the hardness of a material, using a spherical shaped indenter at room temperature. Test Method [E10](#) and ISO 6506-1 provide guidance on the Brinell hardness test, which is based on the measurement of the diameter from the impact of a removed indenter.

4.6.3 Vickers and Knoop are hardness test methods that both use pyramidal shaped indenters, but have different face angles on the indentations, and also specify different ranges of the loading force. Knoop (0.098 N to 19.614 N) could be helpful to determine the micro-hardness of separate inclusions in the structure of additive metals. Test Method [E384](#) and ISO 4545-1 describe the Knoop hardness test. Vickers (0.098 N to 980.07 N) may be helpful in evaluating both the micro- and macro-hardness of additive manufactured metal parts. The Vickers hardness test is described in Test Method [E384](#) and ISO 6507-1. The evaluation of the hardness by Vickers and Knoop is based on the measurement of the diagonal lengths from the impact of the removed indenter.

4.6.4 Test Methods [E18](#) and ISO 6508-1 provide information on the Rockwell hardness test. Both tungsten carbide balls (HRB) and diamond sphero-conical indenters (HRC) can be used for the Rockwell hardness test, which is done at room temperature. One main advantage of this hardness test in comparison to the previously described test methods is Rockwell's ability to measure the indentation depth directly.

4.6.5 The Scleroscope hardness test method, which is a dynamic measurement, is described in Practice [E448](#). This

dynamic indentation hardness test uses a calibrated instrument which then drops a diamond-tipped hammer from a fixed height onto the surface of the test material. The height of the rebound of the hammer is used to measure the hardness of the material. An additional dynamic hardness test is described in ISO 14577-1. One benefit of this test method is its ability to not only determine the plastic hardness, but also the elastic hardness and the indentation modulus, which cannot be determined using the previously mentioned methods.

4.6.6 There are also a wide range of mobile hardness measurement instruments with many potential applications. These instruments are used to determine the hardness when the previously mentioned test methods are not practical (such as due to an inability to take sample to the test instrumentation), or when it isn't possible to make a sample out of the original part. These mobile hardness test instruments are only described in ASTM Standards. Test Methods [B647](#) and [B648](#) cover the mobile Hardness tests by Webster, Barcol and Newage. These techniques have limited applicability and can only be used on aluminum materials.

4.6.7 Approximate conversions between the different hardness tests and indenter shapes are provided in ASTM [E140](#).

4.6.8 ISO TR 29381 summarizes the state of the art in deriving bulk material tensile properties from the indentation response of the material. It describes three techniques: representative stress-strain, inverse finite element analysis methods and the use of statistical approaches. However, all of these techniques assume a test piece that is free of residual stresses.

5. Tests for Measuring Fatigue Properties

5.1 Fatigue:

5.1.1 Both Practice [E466](#) and ISO 1099 can be used for fatigue testing of metals at room temperature. Both standards provide guidelines for an axial force-controlled fatigue test, which is continued until the specimen fails or until a predetermined number of stress cycles has been exceeded. ISO 12106 covers fatigue testing of metal samples where the axial-strain is controlled. This differs from ISO 1099, which is a low-cycle fatigue test that is performed until specimen failure.

5.1.2 Test Method [E606](#) is intended for primarily strain-controlled fatigue tests, in which the magnitude of time-dependent inelastic strains are on the same order or less than the magnitudes of time-independent inelastic strains. In addition, Test Method [E606](#) determines the cyclic stresses and strains any time during the tests and provides guidance to determine the fatigue life.

5.1.3 The method to determine the rate of crack growth on notched specimens is described in Test Method [E647](#) and ISO 12108. The results of this test method determine the resistance of a material against crack propagation under cyclic force test conditions.

5.1.4 Practice [E2368](#) and ISO 12111 cover the determination of thermo mechanical fatigue properties of materials under uniaxial loaded strain-controlled conditions. Test Method [E2714](#) covers the determination of mechanical properties pertaining to creep-fatigue deformation or crack formation. This test is performed at an elevated temperature. It also involves the sequential or simultaneous application of the

loading conditions necessary to generate cyclical damage enhanced by creep deformation.

5.1.5 Test Method **E2760** covers the determination of creep-fatigue growth properties of nominally homogeneous materials by using pre-cracked compact specimens. It involves fatigue cycling with long loading/unloading rates or hold times, or both.

5.1.6 The fretting fatigue test is described in Guide **E2789**. Fretting fatigue is generally characterized by a sharp decrease in fatigue life at the same stress level as that of a standard specimen.

5.1.7 The determination of the fatigue life of a rotating bar while bending is described in ISO 1143. The specimen may be mounted as a cantilever, with a single-point or two-point-loading, or as a beam with a four-point loading. The test is continued until the specimen fails or a pre-determined number of stress-cycles have been achieved.

5.1.8 ISO 1352 covers torque-controlled fatigue testing which is carried out at ambient temperature in air, under constant amplitude angular displacement control, and which leads to failure in a few thousand cycles.

5.2 Fracture Toughness:

5.2.1 The following section involves test methods to determine the fracture toughness which may be applicable to additively manufactured materials. These methods are based on the tension tests and are also referred to as quasi-static tests. There are also dynamic tests, which are used to determine the behavior of the material against abrupt loading.

5.2.2 Test Methods **E399** and **E1820** are the basic ASTM test methods for determining the linear-elastic plain strain fracture toughness of metals. Both methods use a slowly increasing force. Test Method **E399** includes recommendations, requirements, and design information for the testing of the pre-cracked specimens. Test Method **E1820** covers specific procedures and guidance for the determination of the fracture toughness which can be measured by the R-curves or as a point value. ISO 12737 is the equivalent ISO test method of Test Method **E399** and ISO 12135 is the equivalent of Test Method **E1820**. ISO 22889 provides guidelines for specimens that are very small and hence have size sensitivities. Practices **B645**, **B646** and Guide **B909** are ASTM standards that provide supplementary information for the evaluation of fracture toughness of aluminum alloys and the interpretation of their results. Guide **B909** provides additional guidance for fracture toughness tests of aluminum products for which complete stress relief is not practicable. Specimens for the plane-strain fracture test which have a Chevron-shaped-notch are covered in Test Method **E1304**.

5.2.3 The method to determine the plane-strain crack-arrest fracture toughness of ferritic steels is described in Test Method **E1221**.

5.2.4 The crack-tip opening displacement (CTOD) is a value that describes the behavior of a metallic material against the displacement of cracks. The CTOD is used to describe the moment when the crack propagation is changed from stable to unstable. Test Method **E1290** is the ASTM method for CTOD fracture toughness measurements. ISO 27306 is a standard

method to determine the constraint loss correlation of CTOD fracture toughness for fracture assessment of steel component.

5.2.5 Test Methods **E23** covers impact testing to determine the behavior of metal when subjected to multi-axial stresses, coupled with a high loading rate and with either low or high temperatures. This ASTM standard describes the requirements, preparation and qualifying test specimens for both Charpy and Izod methods. ISO 148-1 is the equivalent ISO standard, but includes only guidelines for the Charpy test. An additional ISO standard is ISO 14556, which is similar to the ISO 148-1 but is just applicable for steel materials.

5.3 Crack Growth:

5.3.1 Practice **E740** is the standard for fracture testing with surface-crack tension specimens. The test is performed with a continuously increasing force and sustained loading. This standard also provides the procedure to determine the residual strength of a specimen with a semi-elliptical or circular-segmented fatigue crack.

5.3.2 Test Method **E1457** is a standard for measurement of creep crack growth times in metal specimens that are subjected to static or quasi-static loading condition.

5.3.3 Test Method **E1681** is the standard for determining the threshold stress intensity factor for environmentally-assisted cracking of metallic materials, and requires an environmental chamber.

5.3.4 Test Method **E2472** is the standard for determination of resistance to stable crack extension under low-constraint conditions, which occurs when the crack-length-to thickness and uncracked-ligament-to-thickness ratio are greater than or equal to four.

6. Reporting

6.1 Reporting guidelines should be followed in accordance with each applicable standard mentioned above. However, due to the possibility for anisotropic behavior in metallic parts built via additive manufacturing processes, additional information must be included in the reports. This information includes the specification of the location and orientation of parts within the build volume of the additive manufacturing system described in accordance with **ISO/ASTM 52921**. See also Practice **F2971**.
